A series of model-scale tests were recently completed using the open-rotor propulsion rig at the NASA John H. Glenn Research Center at Lewis Field in an effort to characterize the aeroacoustic performance of several open-rotor-propulsor designs. These included the historical-baseline and second-generation blade sets. Subsequently, the second generation design was assessed to have significant cumulative margins relative to the International Civil Aviation Organization Chapter 4 noise regulations, whilst the historical blade set had a negative margin. However, integrated metrics, like effective perceived-noise level, are not intuitive to the layperson, and likely do not convey the noise benefits over earlier designs, for example, the acoustically unique unducted-fan demonstrator of the 1980s. This paper develops the means of auralizing flyover-noise projections of full scale open-rotor engines using model-scale data in a manner that more readily communicates the noise benefit, and that is consistent with previously published aircraft-system-noise assessments. The effects of thrust level, installation type, and rotor-inflow angle on the generated flyover noise are investigated for the historical-baseline blade set. Finally, the benefits of the modern open-rotor blade design are made apparent through comparison of flyover noise from the second-generation and historical-baseline blade sets.

Nomenclature

c_{Flight}	=	speed of sound at aircraft flight conditions
c_{Tunnel}	=	speed of sound at wind-tunnel-test conditions
$D_{\text{Full Scale}}$	=	diameter of rotor for full scale engine
D_{Rig}	=	diameter of rotor for wind-tunnel model
f_{Flight}	=	frequency of rotor noise at aircraft flight conditions
f_{Static}	=	frequency of rotor noise at static conditions
M_{Flight}	=	flight Mach number
M_{Tunnel}	=	wind-tunnel-test Mach number
P_{Flight}	=	flight static pressure
P_{Tunnel}	=	wind-tunnel-test static pressure
α_{Inflow}	=	rotor-inflow angle
θ_E	=	noise-emission yaw (polar) angle
θ_G	=	geometric sideline microphone-array angle
ρ_{Flight}	=	air density at aircraft flight conditions
ρ_{Tunnel}	=	air density at wind-tunnel-test conditions

I. Introduction

THE increase in jet-fuel costs has prompted renewed research efforts by engine manufacturers in contrarotating open-rotor propulsion systems due to their potential for large reductions in fuel burn relative to contemporary turbofans. Advanced propellers, both single and contrarotation, were studied in the late 1970s and 1980s for their fuel-efficiency benefits as part of the National Aeronautics and Space Administration (NASA) Advanced Turboprop Project [1]. For example, General Electric (GE) had a contrarotation concept called the unducted fan (UDF®). Multiple generations of early UDF blade designs were tested at model scale at GE [2], NASA Lewis Research Center [3], and other locations. Additionally the UDF demonstrator engine underwent extensive ground tests followed by flight tests on two different commercial aircraft [4]. The UDF was memorable for its scimitar-shaped propeller blades and its unique noise signature.

The UDF was successful at demonstrating open-rotor technology in that it achieved its fuel-burn target with acceptable acoustic performance for the regulations at the time. Concept development continued at GE, culminating in the GE36 product design, which was canceled when changing fuel prices no longer supported the business case for further development. However, going forward, noise was still a concern, and the ability to tailor designs for both high efficiency and low noise was limited by the design tools of that era. The current effort takes advantage of contemporary computational fluid dynamics and computational aeroacoustic tools to optimize blade designs for both aeroperformance and reduced noise emissions. NASA, Federal Aviation Administration (FAA), and GE have collaborated to design, build, and test new generations of low-noise high-efficiency open rotors [5,6]. Aerodynamic performance and acoustic measurements from this test series have been used to perform aircraft-system-level analyses for fuel burn and community noise. The new generation of open-rotor designs is predicted to have an effective perceived-noise level (EPNL) of 15–17 EPNdB cumulative margin relative to Chapter 4 noise regulations [7,8] for the NASA modern open-rotor single-aisle aircraft application [5,6,9]. However, community-noise levels based on integrated sound exposure do not adequately capture the remarkable acoustic improvements of the latest generation designs for a layperson. A more natural method of demonstrating the progress in low-noise designs would be aural comparisons of a contemporary

low-noise propulsor design with the corresponding noise of the original UDF demonstrator.

To that end, a new capability was recently developed to auralize aircraft flyover noise. The process entails synthesis of the source noise, propagation of that noise to a ground receiver, and an optional step of casting that noise in a three-dimensional (3-D) simulated environment [10]. The approach has been shown to generate pressure–time histories having aircraft-noise metrics that are consistent with those generated by the NASA Aircraft Noise Prediction Program (ANOPP) [11] system noise-prediction tool. The capability was recently demonstrated for a reference state-of-the-art Boeing 777-like aircraft and an advanced hybrid wing–body configuration [12]. In that work, source-noise definitions used in the synthesis process were obtained from ANOPP semi-empirical models.

Because the source-noise-prediction models for open-rotor engines are a topic of current research [13], the present effort uses the aforementioned wind-tunnel-test data [5,6] as input for the noise synthesis of both the second-generation (Gen-2) concepts, as well as the historical reference blade design. The latter blade was designed for optimal aeroperformance without considering acoustic performance. The approach taken is similar to that previously used for system noise studies based on this data set, and entails processing the model-scale wind-tunnel-test data to full scale under flight conditions [14], with modifications required to separate coherent tonal noise from incoherent broadband noise. The resulting noise-source definition serves as input to the auralization process just as an ANOPP source-noise prediction would.

This paper presents the auralization for a straight and level flyover trajectory of a modern open-rotor propulsor, designed to power a NASA-defined modern narrow-body commercial-aircraft concept. To illustrate the acoustic improvements of the modern open-rotor concepts, the auralized noise spectra focus on the isolated open-rotor propulsor without other engine- or airframe-noise components. The influence of relevant operating conditions and installations is considered for the historical-baseline blade set, including the thrust level, installation (isolated vs pylon mounted), and rotor-inflow angle. Finally, the auralized noise generated by the historical baseline is compared to a corresponding auralization of a Gen-2 modern low-noise blade design.

To ensure consistency with the previously published results, community-noise metrics derived from the resulting pressure–time histories are compared with those generated using the ANOPP Acoustic Data Module with the same underlying data as input. This effort is intended to lay the groundwork for the auralization of flyover noise associated with full aircraft systems incorporating open-rotor propulsors to complement system noise predictions of the same [14].

II. Open-Rotor Acoustic Tests

A. Test Description

Modern open-rotor acoustic testing was conducted at the NASA John H. Glenn Research Center at Lewis Field, on the refurbished open-rotor

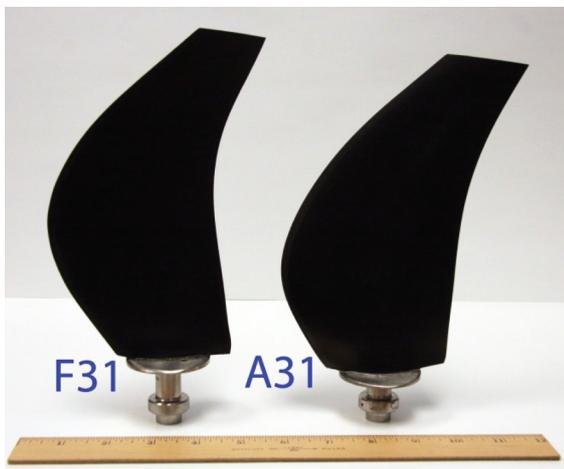

Fig. 1 Historical baseline, F31/A31, blade set.

Table 1 Comparison of key parameters for historical and modern designs (full scale) [5]

Parameter	Historical	Modern

propulsion rig in the acoustically treated 9×15 low-speed wind tunnel (LSWT). The testing was performed at low-speed flight conditions representative of typical aircraft community-noise operations. Data were acquired to characterize both off-design aerodynamic performance and noise emissions at simulated approach, takeoff, and cutback operating conditions. The isolated and simulated installation model configurations were tested. All data used in the present study were acquired at a nominal wind-tunnel Mach number of 0.2.

The historical-baseline blade set, F31/A31, was the legacy blade set used for the measurements presented here. Recent work [15] demonstrated that the F31/A31 is representative of early 1990s aerodesign technology with the resulting noise signature based on the design capabilities of the time. The only compromise for acoustics was associated with the blade count (12 forward × 10 aft). A side view of the blades is shown in Fig. 1. Table 1 shows the key design parameters. See Van Zante et al. [6] for a detailed description of the design parameters. Note that the F31/A31 blade set is different from the earlier 0.72 cruise Mach-number design, called F7/A7, which was flown on the UDF demonstrator aircraft.

Figures 2 and 3 show the F31/A31 blade set in the 9×15 test section in an isolated and a pylon installed pusher configuration, respectively. The primary rotor-performance instrumentation were rotating force balances in each rotor hub to measure the thrust and torque of the rotor system. The forward- and aft-blade rows operated at nominally the same shaft speed. Details of the performance measurements are given by Van Zante et al. [6,16]. Acoustic measurements were acquired at a sideline distance of 152.4 cm (60 in.) at 18 discrete positions (heretofore referred to as “stops”) with the traversing microphone shown in Fig. 2. The nominal geometric angles associated with each stop were measured relative to zero on-axis upstream with 90 deg at the aft pitch change axis, and ranged from 140 (stop 1, downstream) to 17.6 deg (stop 18, upstream). Additional information can be found in Table 2 and Figure 12 of [6]. Emission angles are discussed in the next section. The microphone signal was digitized at 200 kHz for 15 s per directivity angle. The spectra were generated using a 2^{14} -point fast Fourier transform (FFT) resulting in a frequency bin width of 12.2 Hz. Tests were also

Fig. 2 Isolated open-rotor test configuration in the 9×15 LSWT section showing the acoustic traverse microphone at the 152.4 cm (60 in.) sideline position.

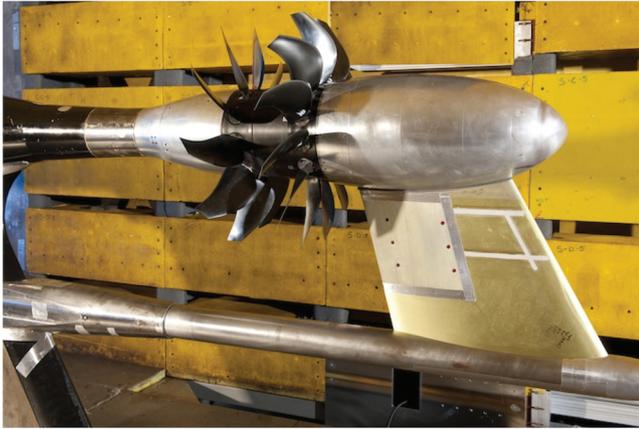

Fig. 3 Close-up photograph of the open-rotor test configuration in the 9×15 LSWT test section with the pylon installed ahead of the rotor system.

conducted to estimate the facility's tare background-noise levels, that is, noise levels at the prescribed flow conditions, but with no power supplied to the open-rotor test article and with no blades attached. The details of the acoustic processing, instrument corrections, atmospheric corrections, etc., are provided by Elliott [17].

B. Data Processing

The model-scale wind-tunnel data were postprocessed for use in ANOPP noise assessments and for auralization. The procedure differs slightly, depending on the particular usage.

1. Tunnel to Flight-Condition Processing

The process developed by Guynn et al. [14] for converting scale-model wind-tunnel acoustic data to full scale flight-condition data was adopted with minor changes for auralization. The process is summarized here. The calibrated microphone-corrected power spectral densities (PSDs) (decibels per hertz) were adjusted to a 1 ft free-field, lossless condition through application of an inverse atmospheric-attenuation model and spherical-spreading-loss correction. At each step, the PSDs of the tare and test data were first converted to narrow-band wind-tunnel sound-pressure levels (SPLs) (decibels) according to

$$\text{SPL} = \text{PSD} + 10 \log_{10}(\Delta f) \quad (1)$$

in which Δf is 12.2 Hz.

The tare data were next removed from the test data to obtain the corrected tunnel measurement, that is

$$\text{SPL}_{\text{Tunnel}} = 10 \log_{10}[10^{(\text{SPL}_{\text{test}}/10)} - 10^{(\text{SPL}_{\text{tare}}/10)}] \quad (2)$$

Table 2 List of nominal geometric and emission angles for Mach 0.2

Stop number	Geometric angle, deg	Emission angle, deg
1	140.0	132.6
2	135.0	126.9
3	127.5	118.3
4	120.0	110.0
5	112.5	101.9
6	105.0	93.9
7	97.5	86.1
8	90.0	78.5
9	82.5	71.0
10	75.0	63.9
11	67.5	56.8
12	60.0	50.1
13	52.5	43.4
14	45.0	36.9
15	37.5	30.5
16	30.0	24.3
17	22.5	18.1
18	17.6	14.2

Note that Eq. (2) will fail if $\text{SPL}_{\text{tare}} \geq \text{SPL}_{\text{test}}$. To avoid that possibility, SPL_{tare} is set to $\text{SPL}_{\text{test}} - 0.5$ when $\text{SPL}_{\text{tare}} > \text{SPL}_{\text{test}} - 0.5$. Low-frequency tunnel noise below 700 Hz (model scale) was removed from the resultant by replacing that data with a quadratic function having a 10 dB attenuation (relative to the level at 700 Hz) at 100 Hz. This noise was associated with the 9×15 LSWT background, not the model; thus, its removal was justified.

The data were next converted from wind-tunnel to static conditions by

$$\begin{aligned} \text{SPL}_{\text{Static}} &= \text{SPL}_{\text{Tunnel}} + 10 \log_{10}[1 - M_{\text{Tunnel}} \cos \theta_E]^{\text{SME}} \\ &\quad - 10 \log_{10}[(\rho_{\text{Tunnel}}/\rho_{\text{ISA}})^2 (c_{\text{Tunnel}}/c_{\text{ISA}})^4] \\ &= \text{SPL}_{\text{Tunnel}} + 10 \log_{10}[1 - M_{\text{Tunnel}} \cos \theta_E]^{\text{SME}} \\ &\quad - 10 \log_{10}(P_{\text{Tunnel}}/P_{\text{ISA}})^2 \end{aligned} \quad (3)$$

in which the second term on the right-hand side removes the effect of convective amplification included in the measured tunnel data, and the third term is a source-strength-amplitude adjustment to correct the tunnel conditions to International Standard Atmosphere (ISA) conditions. Here, M_{Tunnel} and P_{Tunnel} are the Mach number and static pressure averaged over all stops, respectively; the source-motion exponent (SME) is taken as 2 for a dipole source; and the emission angle θ_E is computed from the geometric angle θ_G by

$$\theta_E = \theta_G - \sin^{-1}[M_{\text{Tunnel}} \sin \theta_G] \quad (4)$$

A list of emission angles is also provided in Table 2 for the nominal M_{Tunnel} of 0.2. Note that there is no associated Doppler frequency shift because the relative velocity between the source and the microphone is zero.

The data were next converted from static conditions to flight conditions by

$$\begin{aligned} \text{SPL}_{\text{Flight}} &= \text{SPL}_{\text{Static}} - 10 \log_{10}[1 - M_{\text{Flight}} \cos \theta_E]^{\text{SME}} \\ &\quad + 10 \log_{10}[(\rho_{\text{Flight}}/\rho_{\text{ISA}})^2 (c_{\text{Flight}}/c_{\text{ISA}})^4] \\ &\quad + 10 \log_{10}[M_{\text{Flight}}/M_{\text{Tunnel}}] \\ &= \text{SPL}_{\text{Static}} - 10 \log_{10}[1 - M_{\text{Flight}} \cos \theta_E]^{\text{SME}} \\ &\quad + 10 \log_{10}(P_{\text{Flight}}/P_{\text{ISA}})^2 + 10 \log_{10}[M_{\text{Flight}}/M_{\text{Tunnel}}] \end{aligned} \quad (5)$$

in which the second term on the right-hand side adds the effect of convective amplification for the particular M_{Flight} , and the third term adjusts the source-strength amplitude to correct the static condition to flight conditions for a standard acoustic day (ISA + 18°F). The fourth term on the right-hand side is an additional correction to account for observed increases in source level with freestream Mach number.

When the data are to be used as input to the ANOPP Acoustic Data Module, the Doppler frequency shift

$$f_{\text{Flight}} = f_{\text{Static}}/[1 - M_{\text{Flight}} \cos \theta_E] \quad (6)$$

must be applied. However, this factor is not applied when the data are used as input to auralization because the propagation process simulates the Doppler shift (see Sec. III).

The conversion from model scale to full scale affects both amplitudes and frequencies. The amplitudes were adjusted by the area scale factor

$$\text{SPL}_{\text{Flight@Full Scale}} = \text{SPL}_{\text{Flight}} + 20 \log_{10}[D_{\text{Full Scale}}/D_{\text{Rig}}] \quad (7)$$

and the frequencies were adjusted by the linear scale factor

$$f_{\text{Flight@Full Scale}} = f_{\text{Flight}}/[D_{\text{Full Scale}}/D_{\text{Rig}}] \quad (8)$$

2. ANOPP-Specific Processing

The full scale flight-condition narrowband spectra obtained from Eq. (7) are interpolated at emission angles ranging from 10 to 170 deg

2. Synthesis of Tones

The synthesis of tones is performed in the time domain using an additive technique. Each tone, in general, may be represented as an amplitude- and frequency-modulated cosine wave, as in

$$s_k(t) = a_k(t) \cos(\phi_k(t)) \quad (9)$$

in which $a_k(t)$ is the amplitude envelope of the k th tone, and $\phi_k(t)$ is the phase argument of the k th tone in radians. According to Eq. (9), each harmonic is characterized completely by two parameters: the amplitude and phase functions. The relationship of the time-varying frequency of the cosine term to the phase argument in the single-tone model is described by

$$\phi_k(t) = 2\pi \int_{-\infty}^t f_k(\tau) d\tau + \phi_{o,k} \quad (10)$$

in which f_k is the instantaneous frequency of the k th tone in hertz, τ is a dummy variable of integration, and $\phi_{o,k}$ is the initial phase. This expression for the phase allows for variations in frequency due to changes in operating condition or unsteadiness of the source, as described next. Note that a tone of constant (time-invariant) frequency f will have a phase integral that becomes the familiar $2\pi ft$ argument of a simple harmonic oscillator. The instantaneous frequency may be obtained from Eq. (10) by differentiating with respect to time as

$$f_k(t) = \frac{1}{2\pi} \frac{d(\phi_k(t))}{dt} \quad (11)$$

The tonal amplitudes are varied continuously according to the instantaneous emission angle. The initial phase of each harmonic is randomized. Pressure-time histories are synthesized for contiguous blocks of specified hop size. A continuous waveform is achieved by maintaining phase between subsequent blocks. Changes in the tonal frequencies do not occur within a single set of source-noise data corresponding to one operating condition, but may occur between different operating conditions (e.g., an engine spool up). All tones are summed to obtain the total tonal noise. Note that, while the tonal synthesis can be performed at any sampling rate irrespective of the tonal frequencies, the sampling rate used for the broadband synthesis was used for consistency, necessitating postsynthesis resampling to the audio-sampling rate of 44.1 kHz.

3. Temporal Variations

The source-noise data are generated from time-averaged test data, and are therefore time invariant. Broadband and tonal syntheses based on these models faithfully reproduce the predicted spectra when averaged over time, but lack the temporal variations found in the test data. The absence of temporal variations is observable and may diminish fidelity [23], which, in this context, refers to the accuracy of the synthesized sound when compared to the wind-tunnel recording.

Analyses of jet-noise [24] and tonal fan-noise [22] data obtained from static engine tests have previously been performed to characterize the fluctuations, and these fluctuations were subsequently introduced into the source-noise synthesis. While no such analysis has been performed on the open-rotor test data, it is possible that a similar approach could be taken. However, this is outside of the scope of the present effort.

B. Propagation

Propagation of the source noise to a ground receiver occurs in the time domain through application of a time-dependent gain, time delay, and filter to the source noise [10,20]. The propagation process accounts for spherical-spreading loss, atmospheric absorption, and time delay, as well as optionally including ground-plane reflection. The time-varying nature of these quantities is governed by the propagation path.

The straight-line path between the source and the receiver is computed at evenly spaced emission times corresponding to the synthesis hop size. Spherical-spreading loss is dependent on the slant range, giving a time-dependent negative gain. The time delay is a function of the speed of sound and slant range, and its time rate of

change simulates Doppler shift. Note that this scheme applies at all emission angles, including those ahead of the forward-most stop and aft of the aftmost stop, even though the synthesized source noise does not use modified spectra. Because the time delay is not generally an integer multiple of the audio-sampling rate, fractional-delay processing [25] is required to avoid audible artifacts in the propagated sound. As previously noted, the only accurate and consistent approach between ANOPP and the auralization is to specify a uniform atmosphere to ensure a constant speed of sound along the straight-line propagation path [12].

Atmospheric absorption is accumulated along the straight-line path through the specified atmosphere at each one-third octave-band center frequency. The absorption curve is fit with a 2ⁿ-point spline and converted to a minimum-phase finite-impulse-response filter via an inverse FFT, as described by Rizzi and Sullivan [20]. The filter is slant-range dependent and therefore varies in time with the moving source.

Once the time-dependent gain, time delay, and filter are known, the synthesized signal is propagated by filtering the time-delayed signal in the time domain and applying the time-dependent spreading loss to the result. The propagation stage is performed on a dedicated audio server [26] as part of the NASA Community Noise Test Environment [10] simulator application. The output of the propagation stage is a pseudorecording at the receiver location.

Finally, ground-plane reflection may be optionally applied according to either a hard surface (infinite) or finite impedance boundary [27,28]. In this study, a hard (infinite impedance) boundary is considered. The effect of ground-plane reflection is simulated with an image source. The reflected path is processed in a similar manner to that described previously for the direct path, but with a time-varying delay line, gain, and atmospheric-absorption filter associated with the image ray. The interference caused by the addition of the propagated direct and reflected rays produces a comb-filter effect [29], which alters the spectral content in a time-varying manner as the aircraft moves along its trajectory.

Pseudorecordings of the propagated synthesized noise are postprocessed using the Next Generation Aircraft Noise Prediction Program (ANOPP2) [30] Acoustic Analysis Application Programming Interface (API) to generate A-weighted SPL in decibels (re: 20 μ Pa), tone-corrected perceived-noise level (PNLT), and EPNL for comparison with ANOPP generated metrics. This is possible because engineering units are maintained through the auralization process and because metrics generated using ANOPP and the ANOPP2 Acoustic Analysis API are equivalent.

IV. Results

The noise generated under various operating conditions and installations is next considered for the historical-baseline and Gen-2 blade sets. In particular, the effects of thrust level, installation type (pylon mounted or isolated), rotor-inflow angle, and blade set are investigated. These are first performed for a receiver flush to a hard ground plane to allow the trends to be more easily seen in the SPL and PNLT traces. Two cases are then examined for a receiver above the ground to assess the effect of reflections on the received noise. The range of test conditions considered is presented in Table 3. Subsequent plots and discussion refer to the reading number (denoted as RDG in the plot legends) as shorthand notation for each condition.

For simplicity, flyover noise is simulated for a steady, overhead, and level flight trajectory at Mach 0.25 at an altitude of 500 ft above field elevation. The total length of the flyover is 40,000 ft, and extends 20,000 ft on either side of the receiver. A twin-rotor flight vehicle is considered, adding $10 \log_{10}(2)$ to the open-rotor source noise. No other sources (e.g., engine core, jet, or airframe noise) are considered. A homogeneous atmosphere for a standard acoustic day (ISA + 18°F) is used, and atmospheric absorption is obtained using the American National Standards Institute model with the Zuckerwar update [11]. The ground is considered acoustically hard, and the receiver is either flush to the ground, resulting in a 6.02 dB increase across all frequencies, or at the certification microphone height of 3.937 ft (120 cm). Because of the low-frequency tonal content, the tone-correction penalty for PNLT calculations considers all tones in

Table 3 Open-rotor test conditions investigated

Reading number	Blade set	Installation	Full scale thrust, lbf	α_{Inflow} , deg	Forward BPF, Hz	Aft BPF, Hz

^aGE proprietary data (not available for download).

the 50 Hz–10 kHz one-third octave-band range, that is, it does not disregard tones under 800 Hz one-third octave band as is sometimes done in turbofan applications.

A. Synthesis Validation

As-measured, calibrated, but otherwise uncorrected, model-scale microphone pressure-time history data from reading 361 at stop 1 ($\theta_E = 132.6$ deg) were used to validate the source-noise-synthesis process. In the absence of a full scale recording, this allowed the synthesized sound to be both qualitatively (aurally) and quantitatively compared with the recorded pressure-time history data. The PSD was generated from high-pass-filtered versions of the data with a cutoff frequency of 550 Hz. The process described for separating tonal and broadband components was applied, and the resulting data served as input to the component synthesis. In addition, synthesis of the unseparated PSD was performed to demonstrate the need for treating tones as a coherent noise source.

Shown in Fig. 5 is a comparison of the PSD derived from the synthesized tonal signal with that of the separated measured data for the first 50 SOs. Here, both the PSDs of the synthesized tonal pressure-time history and separated measurement were summed at the SO frequencies plus three spectral lines on either side. Excellent agreement is also noted in the comparison of the PSD derived from the synthesized broadband spectrum and the separated broadband measured data, as seen in Fig. 6.

The synthesized tonal and broadband components are summed to form the total source noise at this directivity angle. The comparison of its PSD with that of the measurement is seen in Fig. 7. The two PSDs compare very well. The PSD of the synthesized noise obtained from only broadband synthesis of the total, unseparated measured PSD also compares very well, but is not shown for clarity. For that synthesis method, the entire spectrum is treated as incoherent broadband noise. While both synthesized spectra compare favorably with the measured PSD, the auralized sounds differ. In particular, the sum of the separately synthesized broadband and tonal noise (Supplemental audio.S1) is nearly indistinguishable from the

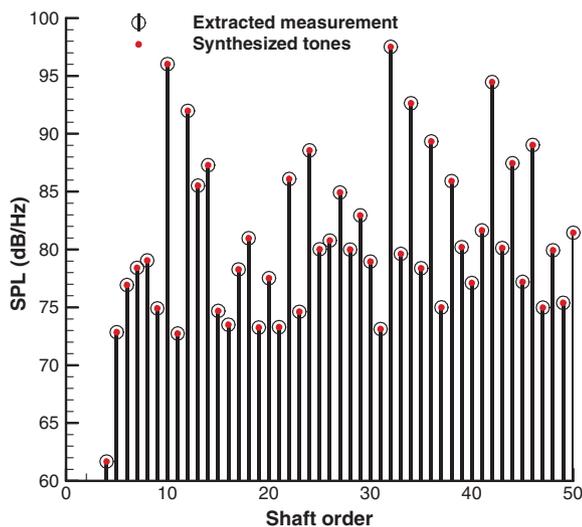

Fig. 5 PSD of synthesized and measured (separated) tonal data for reading 361 (model scale).

measured data (Supplemental audio.S2), while the broadband-only synthesis exhibits an undesirable warblelike artifact (Supplemental audio.S3). The data provided here demonstrate the effectiveness of the method for separating components for synthesis.

B. Effect of Thrust

The effect of thrust on open-rotor flyover noise is considered through comparison of two pylon-mounted zero-inflow-angle conditions: reading 359 with a full scale thrust of 13,741 lbf and reading 361 with a 6.6% higher full scale thrust of 14,650 lbf. The A-weighted SPLs for both flyovers are shown in Fig. 8, in which it is seen that the higher thrust level associated with reading 361 has a

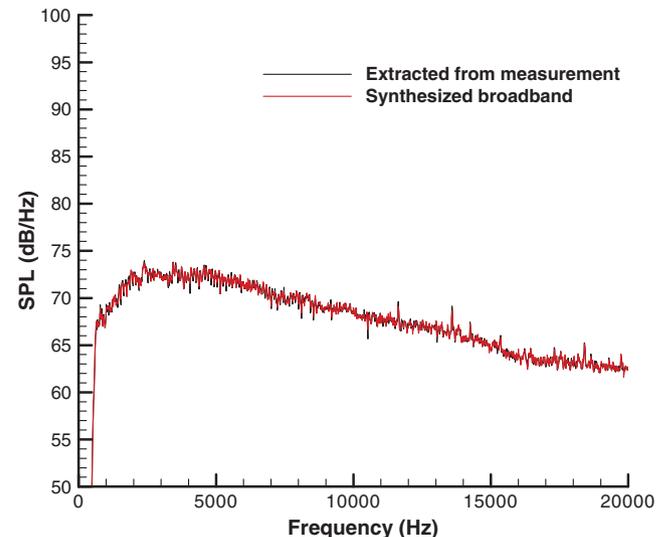

Fig. 6 PSD of synthesized and measured (separated) broadband data for reading 361 (model scale).

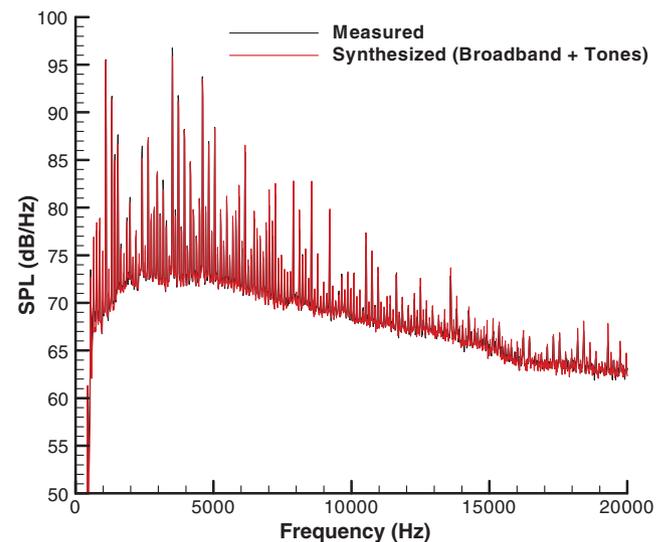

Fig. 7 PSD of synthesized and measured total noise for reading 361 (model scale).

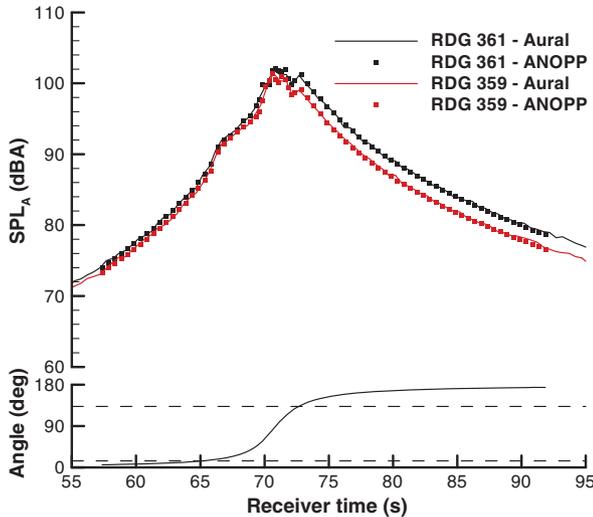

Fig. 8 A-weighted SPL for two flyovers with different thrust levels (flush receiver).

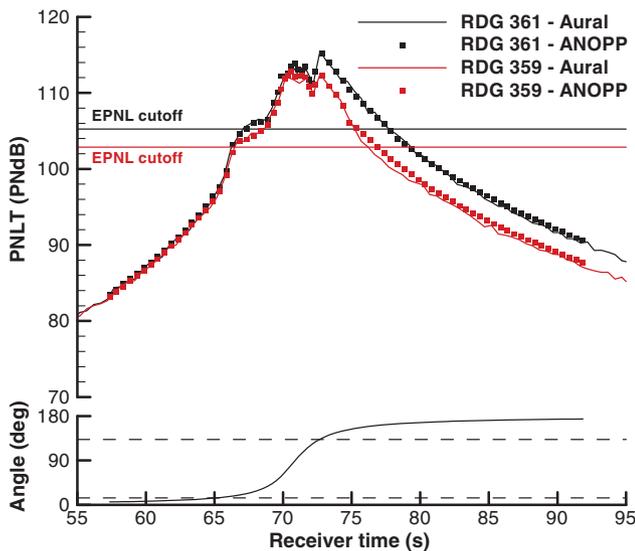

Fig. 9 PNLT for two flyovers with different thrust levels (flush receiver).

small effect at the forward-most emission angle and a greater effect at the aftmost emission angle. The excellent agreement between the auralization and ANOPP analyses demonstrates the compatibility of the two approaches. In Fig. 8 and in subsequent similar plots, the emission angle at the receiver time is shown at the bottom of the plot. The dashed horizontal lines delimit the range of emission angles. Here, it is seen that the second of two peaks in each trace is coincident with the last emission angle, occurring at about 72.8 s receiver time. The decrease from that point on is solely attributable to spreading loss and atmospheric attenuation. This highlights a known limitation of this data set, that is, the aftmost measurement angle may not be sufficiently aft to fully characterize the source directivity.

Next, we consider the PNLT traces shown in Fig. 9. Here, good agreement is shown between the two traces, with small differences attributable to the different methods of propagation: one-third octave band in the case of ANOPP and time domain in the case of the auralization. Also shown are the horizontal lines indicating levels 10 PNdB down from the maximum PNLT. These lines are heretofore denoted as “EPNL cutoff” lines, and are indicated with the same color as the respective reading number. EPNL is calculated using data above these lines. In both cases, a significant portion of the integrated area above each line is aft of the last available emission angle. Notwithstanding this, the calculated metrics compare very well (see Table 4).

Table 4 Effect of thrust on EPNL

Reading number	Full scale thrust, lbf	ANOPP, EPNdB	Auralization, EPNdB
359	13,741	109.3	109.0
361	14,650	111.3	111.3

To gain some insight into the higher noise levels associated with the higher thrust, it is useful to look at a breakdown of A-weighted SPL and PNLT between the tonal and broadband components, as shown in Fig. 10. It is seen that the tonal and broadband contributions are comparable on the approach side, whereas the retreating side is dominated by the tonal contribution. Also noteworthy is the observation that the peak of the broadband-noise PNLT occurs near the 90 deg emission angle and is about 2 EPNdB down from the peak of the tonal noise PNLT, which occurs at the aftmost emission angle. Finally, this type of information is readily available from the auralization process because the two components are synthesized and propagated separately. While such analyses could as well be performed in ANOPP with separated one-third octave-band source spectra, it is not expedient to do so.

The noise metrics in Fig. 10 are useful for indicating that the significant effect of thrust on the retreating side is tone related. To further elucidate this effect, we turn our attention to the non-Doppler-shifted full scale spectral plots in Figs. 11 and 12 for the aft (132.6 deg) and forward (14.2 deg) emission angles, respectively. At the aft emission angle, a greater than 3 dB rise in SPL from the lower thrust level to the higher thrust level is shown for the dominant 1F + 2A combination tone (SO 32 at 689 and 703 Hz). Other tones are comparable in level. A more detailed analysis is required to better understand this phenomenon, but such an undertaking is outside the scope of this paper. At the forward emission angle, a similar trend is seen in the 1F + 2A combination tone, but it is no longer dominant. Other tonal amplitudes are comparable between the two thrust levels; see Fig. 12.

Auralizations of flyover noise associated with readings 359 and 361 are provided as Supplemental audio.S4 and audio.S5, respectively. The reading 361 flyover noise is noticeably louder. An interleaved version, which cuts back and forth between the two readings, is provided in Supplemental audio.S6.

C. Effect of Propulsor Installation

The effect of propulsor installation on open-rotor flyover noise is considered through comparison of two conditions having comparable

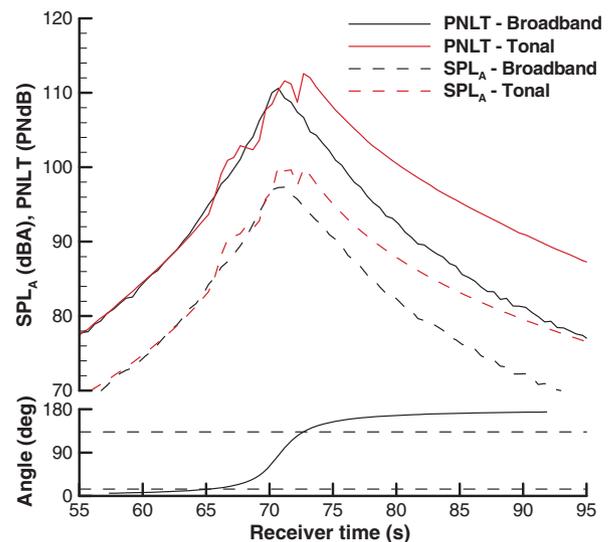

Fig. 10 Breakdown of tonal and broadband metrics from auralization for reading 361 (flush receiver).

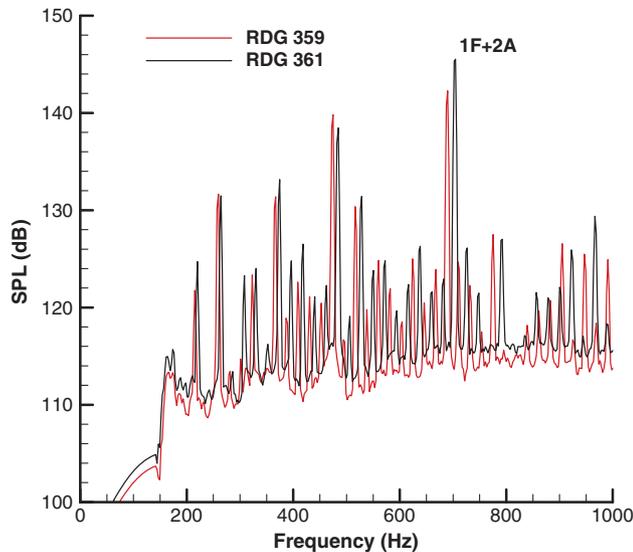

Fig. 11 Effect of thrust on full scale source spectra at the aft emission angle.

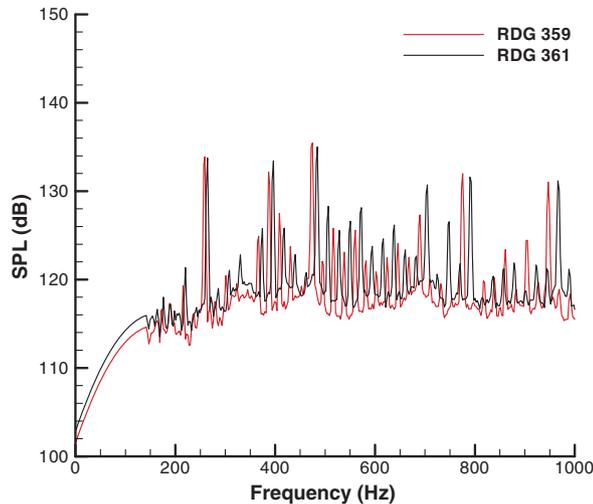

Fig. 12 Effect of thrust on full scale source spectra at the forward emission angle.

thrust (<1% variance) and zero-inflow-angle conditions: reading 359 in a pylon-mounted condition and reading 470 in an isolated condition. The presence of the pylon has a negligible effect on the approach side A-weighted SPL, with significant differences noted only in the last emission angle on the retreating side; see Fig. 13. A similar behavior is noted in the PNL T traces shown in Fig. 14. The ANOPP and auralization traces are consistent, with small differences only seen in the PNL T traces. A penalty of about 1 EPNdB is incurred in the pylon-mounted configuration, as indicated in Table 5.

On the retreating side, the 1F + 1A combination tones (SO 22 at 476 Hz) are comparable for both installations, as seen in Fig. 15. However, the 1F + 2A combination tone (SO 32 at 689 Hz) for the pylon-mounted configuration is almost 4 dB higher than the isolated condition. The harmonics of the forward and aft blade passage

Table 5 Effect of propulsor installation on EPNL

Reading number	Installation	ANOPP, EPNdB	Auralization, EPNdB
359	Pylon	109.3	109.0
470	Isolated	108.1	108.0

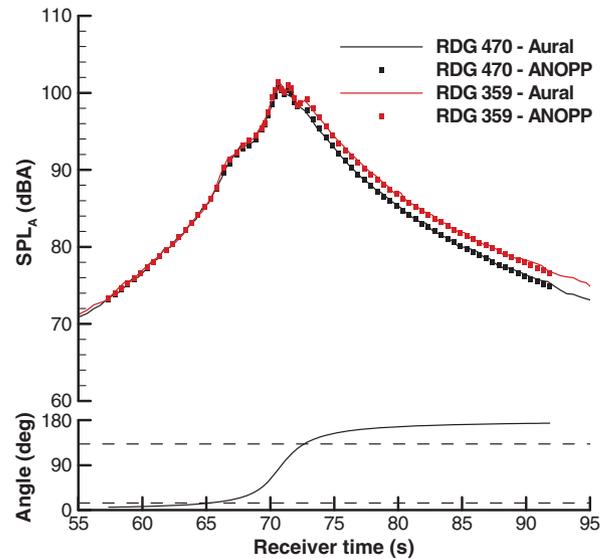

Fig. 13 A-weighted SPL for two flyovers with different propulsor installations (flush receiver).

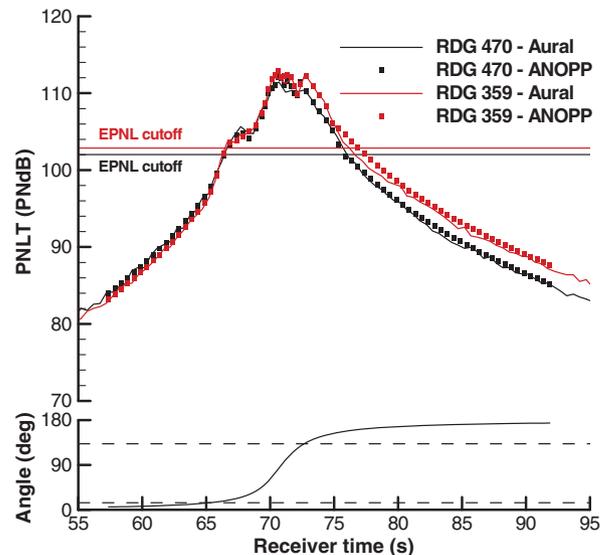

Fig. 14 PNL T for two flyovers with different propulsor installations (flush receiver).

frequency (BPF) tones are also stronger for the pylon-mounted case, notably at 1A (SO 10 at 215 Hz), 1F (SO 12 at 258 Hz), and 2F (SO 24 at 516 Hz), as are most other SO tones. This is consistent with the once per revolution change in loading as the blades pass through the velocity deficit aft of the pylon. On the approach side, the isolated installation has virtually no 1F BPF tone (SO 12 at 260 Hz) or 3F BPF tone (SO 36 at 780 Hz), whereas those tones are strong in the pylon-mounted case; see Fig. 16. Conversely, the 1F + 1A combination tone (SO 22 at 476 Hz) for the isolated case is almost 3 dB higher than the same tone for the pylon-mounted case. A more detailed analysis of the noise-generation mechanisms is outside the scope of this study.

Because of its generally stronger tonal amplitudes, the auralized flyover of the pylon-mounted case sounds both louder and harsher than the isolated case (Supplemental audio.S7). An interleaved version is available as Supplemental audio.S8.

D. Effect of Rotor-Inflow Angle

The effect of the rotor-inflow angle is considered through comparison of three isolated mounting conditions having

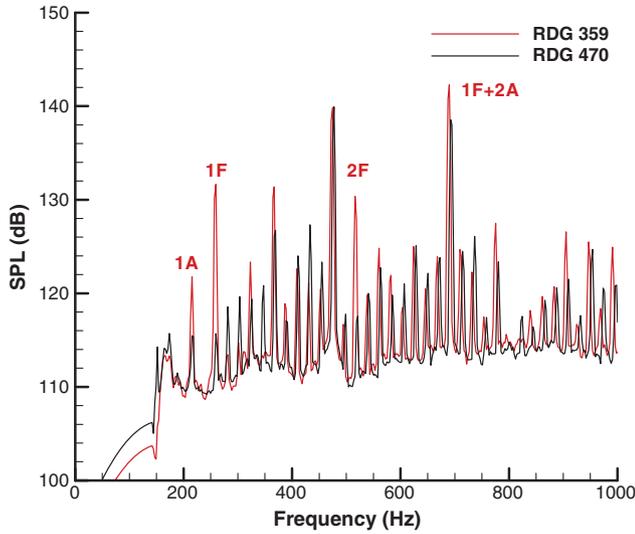

Fig. 15 Effect of propulsor installation on full scale source spectra at the aft emission angle.

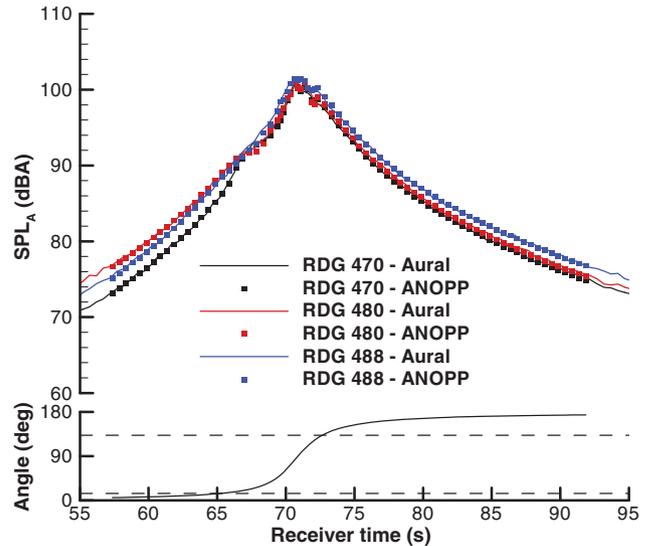

Fig. 17 A-weighted SPL for three flyovers with different rotor-inflow angles (flush receiver).

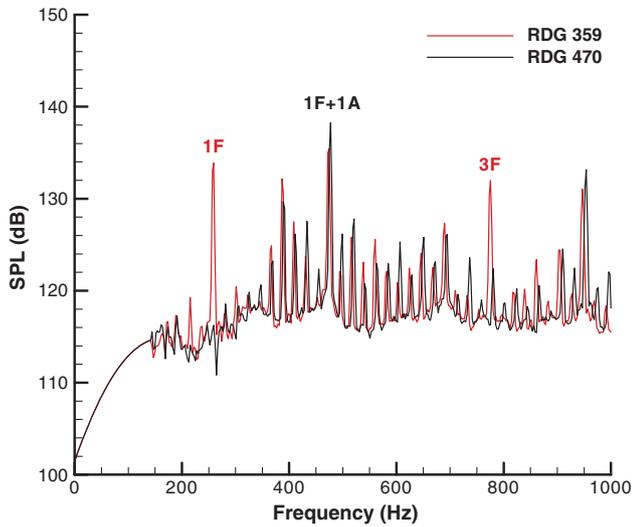

Fig. 16 Effect of propulsor installation on full scale source spectra at the forward emission angle.

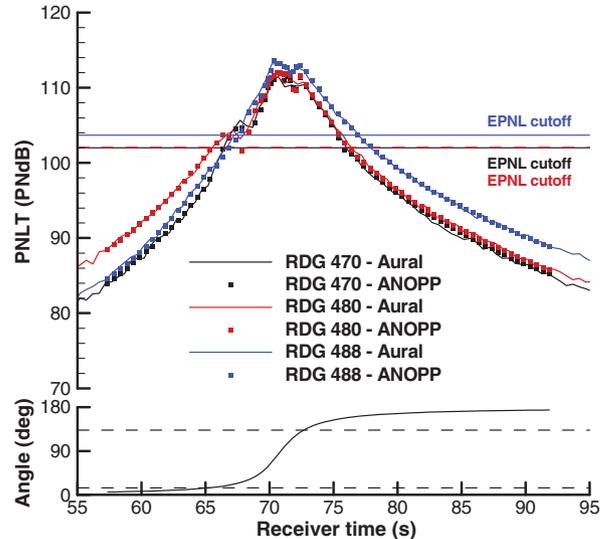

Fig. 18 PNLT for three flyovers with different rotor-inflow angles (flush receiver).

comparable thrust (<1% variance): readings 470, 480, and 488 with $\alpha_{\text{inflow}} = 0, 3,$ and 8 deg, respectively. The rotor-inflow angle is seen to have a significant effect on the A-weighted SPL and PNLT, as shown in Figs. 17 and 18, respectively. Further, unlike the previous cases considered, differences are seen on both the approach side and the retreating side. The significant differences on the approach side are attributable to the forward-emission-angle data (stop 18), which extend from the start of the run until roughly 67.4 s, in which the stop 17 data are used. This behavior has little bearing on EPNL, however, as the data used in that calculation intersect the 10 PNdB down line near the transition point. There is only about a 0.5 EPNdB penalty associated with the 3 deg inflow-angle data, but roughly 1.5 EPNdB additional penalty associated with the 8 deg inflow-angle data; see Table 6.

Table 6 Effect of rotor-inflow angle on EPNL

Reading number	α_{inflow} , deg	ANOPP, EPNdB	Auralization, EPNdB
470	0	108.1	108.0
480	3	108.6	108.4
488	8	110.0	110.0

The full scale source spectra for the forward and aft emission angles are next considered to help explain the flyover metrics. The forward-emission-angle (14.2 deg) spectra are shown in Figs. 19 and 20, and the aft-emission-angle (132.6 deg) spectra are shown in Figs. 21 and 22. Two figures are presented for each angle to provide clarity among the different rotor-inflow angles. The first observation is that the forward angle is dominated by combination tones 1F + 1A (SO 22 at 476 Hz), 1F + 2A (SO 32 at 694 Hz), and 2F + 2A (SO 44 at 954 Hz). While these tones are also significant at the aft angle, the relative contribution of other tones increases.

Focusing now on the forward angle, for the dominant 1F + 1A tone, there is an increase of 6.7 dB as α_{inflow} progresses from 0 (reading 470) to 3 deg (reading 480), but then a decrease of 10 dB progressing to 8 deg (reading 488). Previous research has shown that the rotor-inflow angle has a strong influence on the trajectory of the front rotor tip vortex [31]. The interaction of this vortex with the aft blades is strongly linked to the 1F + 1A tone [5], and this effect appears to be accentuated for the 3 deg (reading 480) rotor-inflow angle. It is clear from its spectrum that the high A-weighted SPL and PNLT levels for the 3 deg (reading 480) rotor-inflow angle are

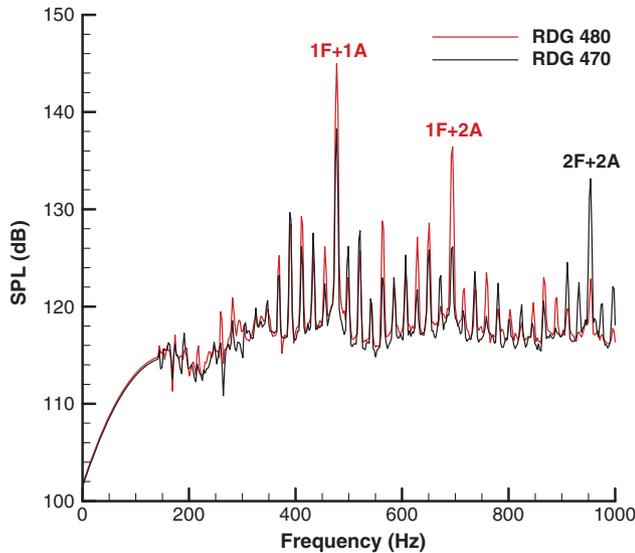

Fig. 19 Full scale source spectra for rotor-inflow angles of 0 and 3 deg at the forward emission angle.

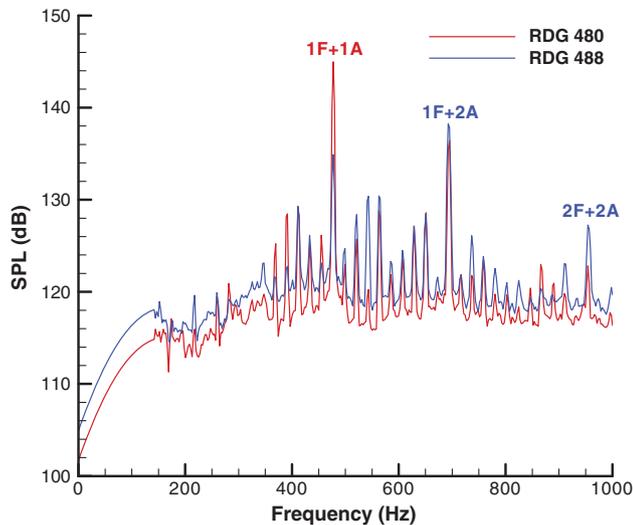

Fig. 20 Full scale source spectra for rotor-inflow angles of 3 and 8 deg at the forward emission angle.

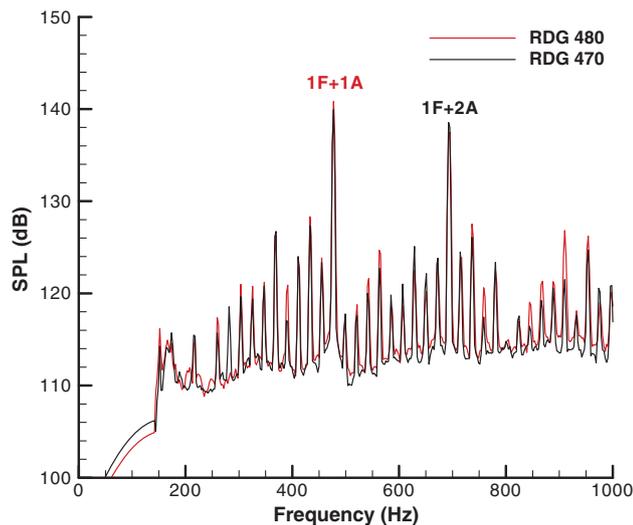

Fig. 21 Full scale source spectra for rotor-inflow angles of 0 and 3 deg at the aft emission angle.

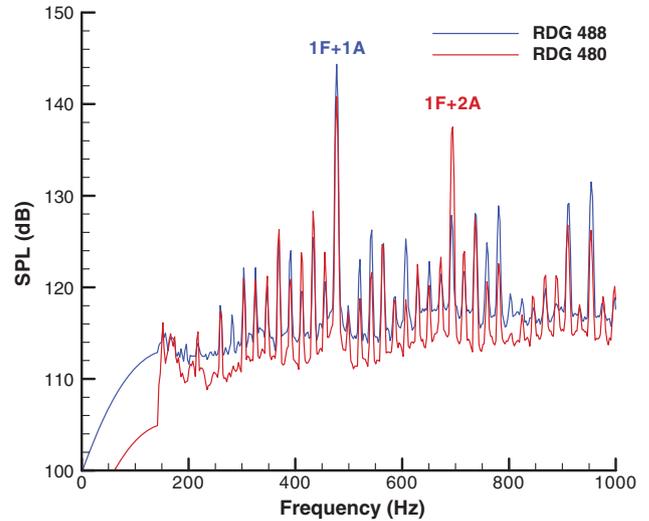

Fig. 22 Full scale source spectra for rotor-inflow angles of 3 and 8 deg at the aft emission angle.

attributable to the $1F + 1A$ tone for the forward emission angle. Note that this behavior is not observed at the aft emission angle, which shows increases of 0.9 and 3.5 dB as α_{Inflow} progresses from 0 (reading 470) to 3 (reading 480) to 8 deg (reading 488) for the $1F + 1A$ tone.

The next most dominant tone is $1F + 2A$, which increases by 9.6 and 2.8 dB as α_{Inflow} progresses from 0 (reading 470) to 3 (reading 480) to 8 deg (reading 488) at the forward angle. At the aft angle, the level of this tone drops by 1.8 and 8.8 dB as α_{Inflow} progresses from 0 (reading 470) to 3 (reading 480) to 8 deg (reading 488). The levels of the other SO harmonics generally increase with increasing inflow angle for the aft emission angle.

The net effect is that the auralized flyovers sound more tonal at nonzero inflow angles than they do at the 0 deg inflow angle on the approach side. On the retreating side, the 0 and 3 deg auralizations sound similar, whereas the 8 deg is more dominated by the lower-frequency $1F + 1A$ tone. Auralizations of flyover noise associated with readings 480 and 488 are provided as Supplemental audio.S9 and audio.S10, respectively. An interleaved version between the three conditions is provided in Supplemental audio.S11.

E. Effect of Ground-Plane Reflections

As noted previously, the effect of a ground-plane reflection produces a time-varying interference between the direct and ground reflected rays, which imparts a sound quality that is distinctive and familiar. Shown in Fig. 23 are the A-weighted SPL and PNLT traces for an elevated receiver at 3.937 ft (120 cm) above ground level for reading 361. In comparison to the relatively smooth traces for the flush receiver (see Figs. 8 and 9), these traces exhibit an irregular shape. The greater difference in EPNL (0.4 EPNdB) between the ANOPP and the auralization methods indicated in Table 7 is largely attributable to differences in the irregularity of the PNLT traces, most of which occurs near the peak and on the retreating side.

A breakdown of tonal and broadband metrics is shown in Fig. 24. Like the flush-receiver breakdown shown in Fig. 10, the approach side has a comparable contribution of tonal and broadband noise, whereas the retreating side is dominated by the tonal component. Indeed, the greater irregularity observed in the tonal A-weighted SPL trace (compared with the relatively smooth broadband noise), in part, translates into greater irregularity in the associated PNLT trace. The greater irregularity in the tonal A-weighted SPL trace relative to the broadband trace has been previously demonstrated to be due to differences in how the propagation is modeled [12]. Specifically, the auralization propagation is performed in the time domain, and thus,

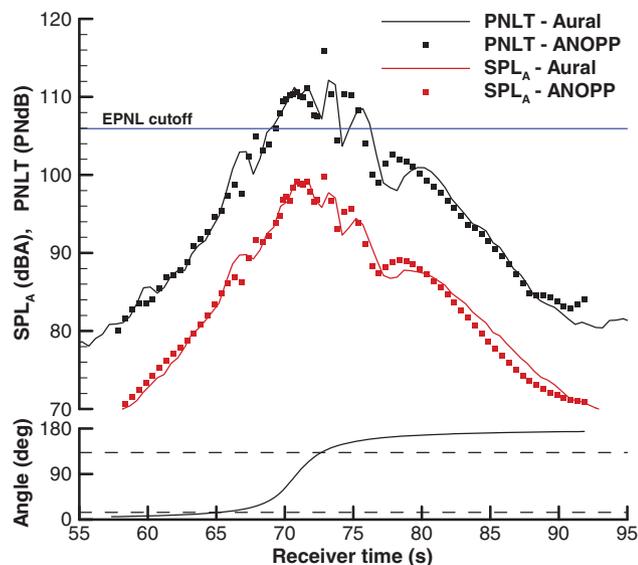

Fig. 23 Effect of an elevated receiver on A-weighted SPL and PNL T for reading 361.

retains the phase relationship between direct and ground reflected rays, while that information is lost in the one-third octave-band implementation within ANOPP. Broadband noise is less sensitive to this phenomenon because the phase distribution is random.

The auralization of flyover noise for reading 361 with ground-plane reflections is provided as Supplemental audio.S12, with an interleaved version of the flush receiver provided in Supplemental audio.S13. The interference effect is particularly pronounced at the overhead angles.

F. Effect of Blade Set

The noise reduction associated with the Gen-2 blade set over the historical baseline is demonstrated for flush and elevated receivers. In particular, the Gen-2 blade-set data used were for a pylon-mounted installation with pylon-wake mitigation, zero-rotor-inflow angle, and high thrust level comparable to historical-baseline reading 361. Because of the proprietary nature of the Gen-2 data, the spectra, A-weighted SPL and PNL T plots and auralizations are not presented. However, the noise reduction for the flush receiver is, on average, 11 EPNdB lower than the F31/A31 blade set, as indicated in Table 7. These results are consistent with previously published results generated independently by NASA [9,14] and GE [5]. Noise reductions, like this, have demonstrated that the Gen-2 design achieved aggressive noise goals, providing 15–17 EPNdB cumulative margin relative to Chapter 4 noise regulations [7,8].

For the flush receiver, the effect of the ground plane is a pressure doubling without interference effects. For the elevated receiver, the interference between the direct and ground reflected rays is present, but the reduction of 10.8 EPNdB, averaged over ANOPP and auralization predictions, is comparable to the reduction found with the flush receiver. In other words, while the character of the sound is greatly affected by the interference due to ground-plane reflections, that has a negligible effect on the reduction of Gen-2 blade-set noise relative to the historical blade set.

Table 7 Effect of blade set (with and without ground-plane interference) on EPNL

Reading number	Blade set	Flush receiver		Elevated receiver	
		ANOPP EPNdB	Auralization, EPNdB	ANOPP, EPNdB	Auralization, EPNdB
361	F31/A31	111.3	111.3	108.5	108.1
Gen-2	Gen-2	100.5	100.2	97.6	97.5

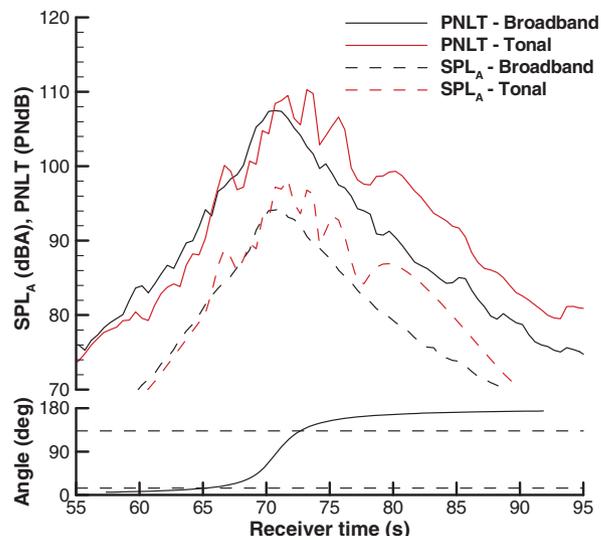

Fig. 24 Breakdown of tonal and broadband metrics from auralization for reading 361 (elevated receiver).

V. Conclusions

A method for auralizing flyover noise using model-scale open-rotor test data has been developed. It is based upon a process developed for system noise assessments [14], but modified to allow noise to be synthesized independently for coherent tonal and incoherent broadband-noise sources. This step is critical for generating open-rotor source noise absent of undesirable artifacts. The synthesized source noise has been shown to have the same spectral characteristics as the narrowband data on which it is based. When propagated through an atmosphere to a ground receiver, the resulting noise metrics were shown to be in excellent agreement with those generated by the ANOPP system noise-prediction tool. Differences in the metric calculations in the presence of a ground plane are understood.

With this auralization capability, a number of investigations were conducted to understand the effects of thrust, installation type, and rotor-inflow angle, and the benefits of a Gen-2 blade set. The effect of increased thrust was found to primarily affect the aft radiated 1F + 2A combination tonal noise, leading to a higher EPNL. The pylon-mounted installation was found to incur a 1 EPNdB penalty over the isolated installation due to higher amplitude tones. Nonzero-rotor-inflow angle was found to increase tonal amplitudes and consequently EPNL by as much as 2 EPNdB. Finally, the Gen-2 blade set was demonstrated to be substantially (11 EPNdB) quieter than the historical-baseline blade set when running at comparable thrust levels. While these conclusions could as well be garnered from the system noise prediction, the true utility of the auralization is its ability to demonstrate noise benefits to stakeholders and practitioners alike, and to understand the psychoacoustic response associated with each configuration. With the gains made in open-rotor noise reduction in recent years, perception-influenced designs are now possible, which both meet noise-certification requirements and simultaneously have desirable sound-quality attributes.

Acknowledgments

This work was performed with support from the Environmentally Responsible Aviation project of the NASA Integrated Systems Research Program and the Fixed Wing and Aeronautical Sciences Projects of the NASA Fundamental Aeronautics Program. The GE Open Rotor blade design and testing were accomplished under the support of the Federal Aviation Administration's Continuous Lower Energy, Emissions and Noise program.
